We discuss the non-Abelian Stokes theorem for SU(2) gauge fields which avoids both additional integration variables and surface ordering. The idea is to introduce the instant color orientation of the flux piercing the loop. The non-Abelian Stokes theorem is also considered on the lattice and various terms contributing to the trace of the Wilson loop are discussed.

Nowadays, there are quite a few formulations of non-Abelian Stokes theorem (NAST) available (for review see, e.g., Ref. [1] and references therein). Generically there exist two principal approaches, the operator [2] and the path-integral [3] one. We consider a new version of non-Abelian Stokes theorem [4] for  $SU(2)$  valued Wilson loops in the fundamental representation. The basic idea is to introduce the instant color orientation of the chromo-magnetic flux piercing the loop, which allows us to avoid the path ordering and represent the Wilson loop phase as an ordinary integral to which Abelian Stokes theorem applies.

Consider Wilson loop  $W(T)$  in the fundamental representation evaluated on a closed contour  $\mathcal{C} = \{x_\mu(t), t \in [0; T], x_\mu(0) = x_\mu(T)\}$ , parameterized by  $x_\mu(t)$ . By definition  $W(T)$  provides a solution to the following Schrödinger like equation

$$\langle \psi(t) | (i\partial_t + A) = 0, \quad (1)$$

$$\langle \psi(t) | = \langle \psi(0) | W(t) = \langle \psi(0) | T e^{i \int_0^t A(\tau) d\tau}, \quad (2)$$

where  $A$  is the tangential component of the gauge potential and  $\langle \psi |$  is a vector in the spin-1/2 irreducible representation space (IRR) of  $SU(2)$  group. Thus the Wilson loop  $W(t)$  can be interpreted as a quantum mechanical evolution operator with the time-dependent Hamiltonian  $H = -A(t)$ . The corresponding state space coincides with spin-1/2 IRR, in which a convenient basis is

provided by generalized (spin) coherent states [5] (see, e.g., Ref. [6] for review). The spin coherent states  $\{|\vec{n}\rangle\}$  are parameterized by a set of unit three-dimensional vectors  $\vec{n}$ ,  $\vec{n}^2 = 1$  and in this basis arbitrary state  $\langle \psi |$  has a unique representation

$$\langle \psi | = e^{i\varphi} \langle \vec{n} |, \quad \langle \vec{n} | g = e^{i\varphi(g, \vec{n})} \langle \vec{n}_g |. \quad (3)$$

Therefore, Eq. (2) becomes

$$\langle \psi(t) | = e^{i\varphi(t)} \langle \vec{n}(t) | = \langle \vec{n}(0) | W(t), \quad (4)$$

where without loss of generality we have taken  $\varphi(0) = 0$ .

Eq. (1) imposes no restrictions on the initial vector  $\langle \vec{n}(0) |$ . However, there exists a distinguished initial state which is of particular importance for the discussion below. Namely, let us take  $\langle \vec{n}(0) |$  to be the eigenstate of the full evolution operator

$$\langle \vec{n}(0) | W(T) = e^{i\varphi(T)} \langle \vec{n}(0) |. \quad (5)$$

Note that generically  $1/2 \text{Tr} W(T) = \cos \varphi(T) \neq \pm 1$  and we assume this from now on. From Eqs. (1,3) it follows that [7]

$$\varphi(T) = \int_0^T \left( \langle \vec{n} | A | \vec{n} \rangle - i \langle \vec{n} | \partial_t | \vec{n} \rangle \right) dt. \quad (6)$$

Using standard properties of the spin coherent states [6] one can represent (6) in vector-like notations

$$\begin{aligned} & 1/2 \text{Tr} W(T) = \\ & = \cos \left[ \frac{1}{2} \int_{\mathcal{C}} \vec{n} \vec{A} dt + \frac{1}{4} \int_{\mathcal{C}} \vec{n} \cdot [\partial \vec{n} \times \partial \vec{n}] d^2 \sigma \right] = \\ & = \cos \left[ \frac{1}{4} \int_{\mathcal{C}} \{ \vec{n} \vec{F}_{\mu\nu} + \vec{n} \cdot [D \vec{n} \times D \vec{n}] \} d^2 \sigma \right], \end{aligned} \quad (7)$$

where  $\vec{n}(t) \in \mathcal{C}$  has been smoothly extended to  $\vec{n}(\sigma) \in S_{\mathcal{C}}$ ,  $D_{\mu}^{ab} = \delta^{ab}\partial_{\mu} - \varepsilon^{acb}A_{\mu}^c$  is the covariant derivative and  $F_{\mu\nu}^a = \partial_{\mu}A_{\nu}^a - \partial_{\nu}A_{\mu}^a - \varepsilon^{abc}A_{\mu}^bA_{\nu}^c$  is the non-Abelian field strength.

By construction the state  $\langle \vec{n}(t) |$  is an eigenstate of  $W^{+}(t)W(T)W(t)$ . Thus  $\vec{n}(t)$  is the instant color orientation of the flux piercing the loop  $\mathcal{C}$ . Since  $\mathcal{C}$  is not infinitesimal the color direction of the flux varies with  $t$ .

The assignment of the vector field  $\vec{n}(t)$  to a given closed path  $\mathcal{C}$  is unique only up to the sign since Eq. (5) possesses two solutions

$$\langle \pm \vec{n}(0) | W(T) = e^{\pm i\varphi(T)} \langle \pm \vec{n}(0) |. \quad (8)$$

However, this sign ambiguity is only global: if  $\langle \vec{n}(0) |$  is an eigenstate with  $\varphi(T) > 0$ , then for any  $t \in [0; T]$   $\langle \vec{n}(t) |$  is an eigenstate of  $W^{+}(t)W(T)W(t)$  with the same positive phase. Therefore there is only a global freedom to change  $\vec{n}(t) \rightarrow -\vec{n}(t)$  for all  $t$  simultaneously.

It is amusing to note that Eq. (7) looks similar to the non-Abelian Stokes theorem of Ref. [3]. We conclude therefore that the path integral of Ref. [3] is exactly saturated by the two particular trajectories  $\pm \vec{n}(t)$ . It is worth mentioning however that Eq. (7) does not correspond in general to any semi-classical approximation.

Notice that Eq. (7) is still not uniquely defined since the vector field  $\vec{n}(t)$  may be extended arbitrarily from  $\mathcal{C}$  to  $S_{\mathcal{C}}$ . The only requirement is that the extension  $\mathcal{C} \ni \vec{n}(t) \rightarrow \vec{n}(\sigma) \in S_{\mathcal{C}}$  must be continuous and the distribution  $\vec{n}(\sigma)$  must agree with  $\vec{n}(t)$  at the boundary  $\delta S_{\mathcal{C}} = \mathcal{C}$ . On the other hand, Eq. (7) is applicable to any infinitesimal area element of  $S_{\mathcal{C}}$  and therefore naturally defines the direction of  $\vec{n}(\sigma)$ . Then the only problem is the choice of sign of  $\vec{n}(\sigma)$ . Here the continuity requirement becomes crucial. Indeed, since the surface  $S_{\mathcal{C}}$  is assumed to be smooth the field  $\vec{F}\delta\sigma$  is continuous on  $S_{\mathcal{C}}$  and hence  $\vec{n}(\sigma)$  being the eigenstate of  $1 + i\vec{\sigma}\vec{F}\delta\sigma$  might be defined continuously as well.

The derivation of the non-Abelian Stokes theorem on the lattice may found in Ref. [4]. The final result

$$\varphi_w = \sum_{x \in S_{\mathcal{C}}} \varphi_x + \sum_{x \in S_{\mathcal{C}}} \Omega_x + \sum_{x \in \mathcal{C}} \alpha_x \quad (9)$$

Fig. 1

is illustrated on Fig. 1. It is understood that phases  $\varphi_w, \varphi_x$  are calculated via Eq. (5).  $\varphi_w$  is the phase of the large Wilson loop,  $1/2 \text{Tr } W(\mathcal{C}) = \cos \varphi_w$ , where  $\mathcal{C}$  is the planar  $2 \times 2$  closed contour bounding the surface  $S_{\mathcal{C}}$ . The first term on the r.h.s. ('dynamical part') is the sum of contributions coming from four 'internal' plaquettes belonging to  $S_{\mathcal{C}}$ . In particular,  $1/2 \text{Tr } U_{p_x} = \cos \varphi_x$ ,  $p_x = 0, \dots, 3$ , where  $U_{p_x}$  is the corresponding plaquette matrix. The second term ('solid angle') comes from the points common to four different 'internal' plaquettes. By construction there are four color vectors per plaquette situated at plaquette's corners. Then  $\Omega_x$  is the oriented solid angle between four vectors at point  $x$ . The third term ('perimeter contribution') is analogous to the second one. It accounts for the difference in color direction between the states on the nearest to the loop 'internal' plaquettes and the states on the loop itself.

Eq. (9) has a simple physical interpretation. The magnitude of the total flux,  $\varphi_w$ , piercing large closed contour  $\mathcal{C}$  is the sum of several terms. The first term sums up the magnitudes of elementary fluxes penetrating the surface  $S_{\mathcal{C}}$ . Since the theory is non-Abelian each elementary flux has its own color orientation which is no less important than the flux magnitude. The other terms in Eq. (9) take into account the difference in color orientation of various fluxes on  $S_{\mathcal{C}}$  as well as of the total flux piercing  $\mathcal{C}$ .

One can show [4] that in the limit  $a \rightarrow 0$  Eq. (9) formally reproduces Eq. (7). Moreover, the 'dynamical part' and 'solid angle' correspond to two terms under cosine in Eq. (7), while the 'perimeter' contribution provides correct boundary conditions. However, this conclusion is only valid for  $\vec{n}_x$ ,  $x \in S_{\mathcal{C}}$  continuous across the plaquette

boundaries. This suggests a natural way to fix the relative sign of eigenstates on neighboring plaquettes analogously to the continuum considerations. Namely, we propose to fix the particular distribution of eigenstates by the requirement that

$$R = \sum_{x \in S_C} |\Omega_x| + \sum_{x \in \mathcal{C}} |\alpha_x| \quad (10)$$

takes the minimal possible value (it is assumed, of course, that eigenvectors at the boundary  $\vec{n}(t) \in \mathcal{C}$  are held fixed from the very beginning). This prescription fixes completely and unambiguously all the states  $\vec{n}(\sigma) \in S_C$  provided that the functional  $R$  has a unique minimum. The uniqueness of the minimum of  $R$  is a separate issue and we have no analytical methods to investigate it. However, at least numerically the minimum of (10) might be approximated with high accuracy.

We performed simple lattice experiments with Eq. (9) in pure SU(2) lattice gauge theory on  $12^4$  lattice at  $\beta = 2.4$  using the standard Wilson action. Since the decomposition (9) is gauge invariant it is legitimate to ask what are the expectation values

$$\begin{aligned} \langle \exp\{i \sum_{x \in S_C} \varphi_x\} \rangle &\sim e^{-TV_{dyn}(R)}, \\ \langle \exp\{i \sum_{x \in S_C} \Omega_x\} \rangle &\sim e^{-TV_{solid}(R)}, \\ \langle \exp\{i \sum_{x \in \mathcal{C}} \alpha_x\} \rangle &\sim e^{-TV_{perim}(R)}, \end{aligned} \quad (11)$$

where we have restricted ourselves to the consideration of rectangular  $T \times R$ ,  $T \gg R$  loops only. Notice that  $T, R$  dependence of Eq. (11) is an ad hoc assumption which has to be checked separately. However, we have found that (11) indeed accurately describe numerical data. The details of simulations may be found in Ref. [4]. The final result is shown on Fig. 2, where the solid curves are drawn to guide the eye.

There are few striking features of the expectation values (11) to be mentioned here. First of all, the 'perimeter' potential turns out to be practically  $R$ -independent:

$$V_{perim}(R) \approx const, \quad (12)$$

which might indicate that the perimeter contribution drops out in Wilson loop VEV. Secondly, both  $V_{dyn}(R)$  and  $V_{solid}(R)$  are rising linear albeit with larger slope than the full potential

$$\sigma_{dyn} \approx \sigma_{dyn} \approx 1.6 \sigma_{SU(2)}. \quad (13)$$

Fig. 2

Moreover,  $V_{solid}(R)$  is strictly linear starting from the smallest possible distance  $R = 2$ . The existence of a linearly rising term in the heavy quark potential at short distances has been widely discussed in the literature, see, e.g., Refs. [8] and references therein.

Finally, we emphasize that there is no factorization for Wilson loop VEV:

$$V(R) \neq V_{dyn}(R) + V_{solid}(R) + V_{perim}(R). \quad (14)$$

However the linear term  $V_{solid}$  might survive at small distances since the 'solid angle' contribution (11) is formally not suppressed by the action even at very large  $\beta$ .
